Noninvasive ventilation (NIV) has been increasingly used in acute care setting with various indications but its use in patients with acute hypoxemic respiratory failure (AHRF) is controversial. Although spontaneous patient activity during mechanical ventilation (MV) may reduce the likelihood of ventilation-perfusion mismatch, especially in dependent regions, close to the diaphragm, high transmural vascular and transpulmonary pressure swing may worsen vascular leakage and increase tidal volume (Vt), leading to self-inflicted lung injury (SILI). From the clinical side, expiratory Vt of 6 mL/kg used in invasive MV during lung protective ventilation is almost impossible to achieve in most of the patients receiving NIV for AHRF. This is particularly important in de novo AHRF patients undergoing NIV, since large expiratory Vt may be generated in assisted pressure controlled modes by the ventilator pressure and by the respiratory muscles.

In this setting, reliable monitoring of Vt and unintentional leaks is of the utmost importance. When using an intensive care unit (ICU) ventilator driven by high pressures in the double-limb configuration, leaks are computed as the difference between inspired and expired Vt. As a consequence, the amount of Vt that the patient gets is usually quantified as expiratory Vt.

However, some points need to be clarified:

1) One characteristic of unintentional leaks is that they are dynamic, which means they can abruptly change during the inspiratory or expiratory phase of the respiratory cycle (even cycle by cycle). Therefore, expiratory Vt measurements using masks may cause concern, because measurements may become unreliable, unstable and difficult to continuously monitor {Carteaux:201dg}, where there may be unintentional expiratory leaks;

2) Although there is a strong belief that preset Vt is equal to the real delivered Vt, in volume controlled mode using ICU ventilator driven by high pressures, on study found that Vt indicated by the ventilator was lower than the delivered Vt, with a difference that was often greater than 10% of the preset Vt. This is also true during pressure controlled mode using NIV, where the direct measurement of flow (and its integration over the time, namely Vt) by the pneumotachograph inside the ventilator, needs to be corrected for the compressible volume. This is the amount of gas which is compressed in the cir-

Abbreviations: AHRF, acute hypoxemic respiratory failure; CPAP, continuous positive airway pressure; ICU, intensive care unit; ILC, intentional leak single-limb vented circuit; IMV, invasive mechanical ventilation; MV, mechanical ventilation; NIV, noninvasive ventilation; SILI, self-inflicted lung injury; TDV, turbine driven NIV ventilator; Vt, tidal volume.

circuit and in the mask (the greater the internal volume of the mask the higher the compressible volume) for each cmH2O of pressure delivered by the ventilator during inspiration. Although most of ICU ventilators are usually equipped with algorithms to calculate and compensate for the compressible volume of the circuit, they do not compensate for the mask internal volume or compliance.

Many companies manufacture dedicated turbine driven NIV ventilators (TDV) with a high pressure O2 inlet to preset a given FiO2 and an intentional leak single-limb vented circuit (ILC), where V̇ is not measured but estimated. Although this circuit configuration is extensively used, the accuracy of V̇ estimate depends on many factors, including the pressure decrease across the limb, especially where there are high unintentional leaks. This is the reason why some ventilators use a mathematical algorithm to calculate this pressure drop or they still measure pressure close to the mask. Finally, the V̇ and leakage estimation in the presence of random leaks remains a challenge when using ILC. However, V̇ estimation has been found to have around 15% when compared to the real measured V̇ in restrictive disorders. This means that, when 500 ml of volume are generated, estimates may be around ± 75 ml, a bias not significantly different from the one measured by many pneumotachographs inside the ventilator.

They may also allow better patient-ventilator synchrony than ICU pressure driven ventilators, even when coupled with their NIV algorithms. Accuracy in estimating leakage is also crucial to improve patient-ventilator synchrony, especially when pneumatic (flow) trigger systems are used. Most of these systems automatically change their sensitivity level according to leakage estimates to avoid trigger asynchronies (autotriggering or ineffective efforts).

Another important concern during NIV in de novo AHRF is that, compared to IMV, it cannot often be used continuously on a daily basis. Although the use of total face mask may increase patient’s tolerance and compliance to NIV and decrease unintentional leaks, the likelihood of maintaining patients under NIV with a mask round the clock for days is remote.

An alternative interface is the helmet, which consists of a transparent hood covering the patient’s whole head with a soft collar neck seal. It is kept in place by two armpit belts or by an annular extendable plastic ring positioned under an inflatable cushion that eliminates the need for armpits straps. Helmet NIV resulted in higher levels of positive end expiratory pressure (PEEP) and a lower intubation rate in patients with AHRF in a single randomized controlled trial. This study suggests that the helmet may allow more time on

Figure 1 Modulating tidal volume in NIPPV/CPAP spontaneous breathing patients can reduce SILI.

Mechanism of reducing SILI through measuring and modulating V̇ during round the clock cycles of mechanical ventilation with helmet interface.

CPAP: Continuous positive airway pressure; NIPPV: Noninvasive positive pressure ventilation; SILI: Self-induced lung injury.

NIV, at higher PEEP, compared to mask NIV, possibly resulting in a lower rate of endotracheal intubation. However, although interesting in term of comfort and in avoiding skin breakdown, the helmet has restrictions in measuring V̇ due to its mechanical properties.

We recently tested the hypothesis that TDV coupled with a single limb ILC, setting intentional leak location at the helmet expiratory port, would provide patient’s V̇ estimates. This configuration allows using the helmet even in
continuous positive airway pressure (CPAP) mode without additional rebreathing, as in ICU ventilator in double limb configuration. Results of the bench simulation in restrictive conditions (Table 1) show that we could potentially use helmet NIV knowing V1. Differences in V1 between TDV and lung simulator remained stable across different tested leak flows.

This feasibility bench and human study demonstrated that estimating V1 during helmet NIV seems to be feasible and accurate in restrictive conditions. Although there are now questions about use of NIV in AHRF, the possibility of continuous noninvasive support for patients, knowing V1, even in CPAP mode, could open new scenarios (Fig. 1), especially in “difficult-to-treat” hypoxemic patients, such as in major burns or in the immunocompromised. Further clinical studies are required to verify this method.
